20	
21	Abstract
22	The current study aimed using a two-experiment musculoskeletal simulation-based approach,
23	measuring ACL biomechanics, knee joint kinematics and lower extremity joint loading to
24	examine the effects of both a prophylactic knee sleeve on 1. a sport specific change of direction
25	movement in female footballers and 2. a single leg landing in male footballers. Experiment 1

26	examined 12 female university first team level footballers (age $20.2 \pm 1.34$ years, height
27	$1.61 \pm 0.06$ m, body mass $57.2 \pm 5.6$ kg) undertaking a $45^{\circ}$ cutting movement in sleeve and no-
28	sleeve conditions. Experiment 2 examined 10 male university first team level footballers (age
29	$21.1 \pm 1.13$ years, height $1.77 \pm 0.1$ m, body mass $71.9 \pm 8.6$ kg) undertaking a single leg drop
30	jump landing in sleeve and no-sleeve conditions. In each experiment, data was collected in a
31	biomechanics laboratory and three-dimensional motion capture and ground reaction force
32	information was collected. Three-dimensional kinematics, three-dimensional knee kinetics and
33	ACL ligament forces/ strains were measured using musculoskeletal simulation, and
34	participants were also asked to subjectively rate the knee sleeve in terms of both comfort and
35	stability. Experiment 1 showed that the sleeve condition was associated with greater ACL strain
36	(sleeve = 13.57% and no-sleeve = 10.26%) and forces (sleeve = 1.19BW and no-sleeve =
37	0.94BW). In addition, the brace condition also enhanced lateral compressive tibiofemoral
38	(sleeve = $4.70BW$ and no-sleeve = $4.20BW$ ) and total compressive tibiofemoral force (sleeve
39	= 11.73BW and no-sleeve = 11.08BW). Finally, for the subjective ratings, participants
40	indicated that the knee sleeve significantly improved perceived comfort and stability.
41	Experiment 2 did not reveal and statistical differences between knee sleeve and no-sleeve
42	conditions, nor any effects of the knee sleeve on subjective ratings of comfort or stability.
43	Therefore, the findings from the current investigation suggest that the prophylactic knee sleeve
44	examined in the current investigation does not appear to reduce the biomechanical parameters
45	linked to the aetiology of knee pathologies in male/ female footballers.

# 47 Introduction

Football is regarded as the most popular sport in terms of audience and participants, with more
than 200,000 professional and over 240 million amateur players globally <sup>1</sup>. Football like most
other team sports is characterized by intermittent deceleration and landing activities requiring

rapid and agile change of direction movements <sup>2</sup>. As both a competitive and recreational activity, football is associated with a plethora of physical benefits including enhanced cardiovascular, mental and bone health <sup>3</sup>. However, football is also connected with a relatively high incidence of injury <sup>4</sup>, which has been shown to exert a significant burden on socioeconomic and healthcare systems <sup>5</sup>. Epidemiological investigations in professional players have shown injury rates of 8.0 per 1000 h and an average of 2.0 injuries per season <sup>6</sup> and 38.56 per 1000 h, at a rate of 0.85 time-loss injuries per match in recreational players <sup>7</sup>.

58

59	One of the most commonly injured musculoskeletal structures in football is the knee <sup>6,7</sup> , and
60	the anterior cruciate ligament (ACL) is the most frequently injured knee ligament <sup>8</sup> . The ACL
61	itself is vital for the provision of knee stability during the dynamic activities associated with
62	football <sup>9</sup> . With its unique functional properties, attachment points and complex anatomy, the
63	ACL is highly effective in restraining both excessive anterior tibial translation and coronal/
64	transverse plane knee motions <sup>10</sup> . ACL injuries in football players are predominantly, non-
65	contact in nature, in that the ligament becomes injured without physical contact between
66	players <sup>11</sup> .

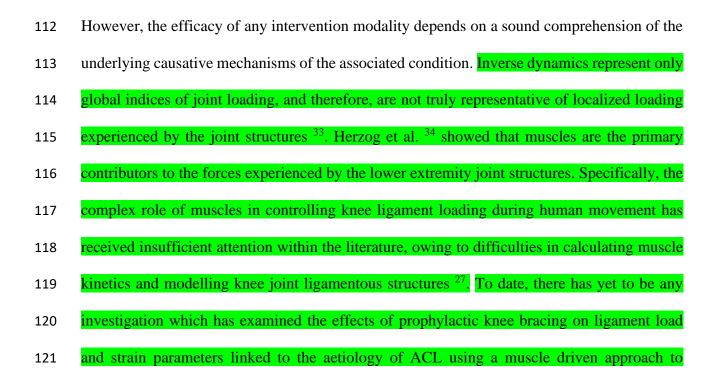

68	Physiologically, ACL injuries occur when the ligament experiences excessive tensile forces
69	and strains <sup>12</sup> . As the ACL serves primarily to resist anteriorly directed tibial translation in
70	addition to knee valgus and internal/ external rotation movements; in vivo and in vitro
71	investigations have shown that it experiences both load and strain during activities that involve
72	these mechanisms <sup>13</sup> . Aetiological investigations support this, in that the ACL is most
73	commonly disrupted in the period immediately following foot contact, in athletic tasks
74	involving sudden decelerations, landings and cutting manoeuvres <sup>14</sup> . Injury to the ACL is

extremely serious in competitive players, and typically leads to long term absence from football
<sup>15</sup>. ACL pathologies typically require reconstructive intervention using auto/allografts in order
to provide sufficient stability to the injured knee to allow return to training/ competitive
activities <sup>16, 17</sup>. Silvers & Mandelbaum <sup>18</sup> showed that over 250,000 ACL reconstruction
interventions are undertaken each year in the US alone with average allocated costs exceeding
\$2 billion.

81

Importantly, the ACL can be associated with poor healing capacity, and the risk of a second 82 injury is as high as 30% in the ipsilateral knee and 11% in the contralateral side <sup>19, 20</sup>. Even 83 after full recovery, ACL injuries frequently lead to chronic knee pain, and athletes who 84 experience an ACL pathology are up to ten times more susceptible to early-onset degenerative 85 knee osteoarthritis<sup>21</sup>, leading not only to a decline in athletic participation but also enduring 86 disability in later life <sup>22</sup>. Radiographic knee osteoarthritis significantly reduces health-related 87 88 quality of life, and degenerative joint disease secondary to ACL injury imposes further economic burden <sup>23</sup>. Similarly, it has been demonstrated that psychological as well as physical 89 wellbeing is negatively affected, and ACL injuries have been associated with anxiety, self-90 esteem, pain response, depression, and feelings of decreased athletic identity <sup>24</sup>. Importantly, 91 previous analyses have shown that many footballers fail to return to their previous levels of 92 athletic function, as statistically significant performance decrements have been observed in 93 relation to non-injured controls <sup>25</sup>. Concerningly, both Roos et al., <sup>26</sup> and Walden et al., <sup>15</sup> 94 demonstrated that only 30-35% of competitive footballers remained active 3 years after 95 96 suffering an ACL injury.

Because of the high incidence of ACL injuries in football players <sup>15</sup> and the poor-long term 98 prognosis following injury, prophylactic interventions are therefore a key clinical priority <sup>27</sup>. 99 Knee braces are external devices constructed in order to improve three-dimensional knee joint 100 dynamic alignment <sup>28</sup> and range from semi-rigid devices incorporating uni or polyaxial hinges 101 to more compliant sleeves designed simply to provide compression and enhance proprioception 102 <sup>29</sup>. Knee braces represent a conservative and relatively low-cost external apparatus that are 103 minimally invasive/ restrictive such that they can be worn during high-intensity sports 104 maneuvers <sup>28</sup>. Prophylactic knee braces have been shown to reduce transverse plane knee range 105 of motion during run, cut and vertical jump movements in netball players <sup>28</sup>, peak knee 106 adduction moment during a badminton lunge <sup>30</sup> and patellar tendon loading in run, cut and 107 single leg hop movements in female athletes <sup>31</sup>. Furthermore, Sinclair et al. <sup>32</sup> showed using an 108 109 inverse dynamics-based method of quantifying ligament loading, that ACL load rates were significantly reduced during single leg hop landings and cut movements. 110

quantify knee mechanics. This is principally due to the inability to non-invasively quantify
 ACL loads and strains during high-risk sports movements <sup>35</sup>.

124

Recent, advances in musculoskeletal simulation software alongside enhancements in 125 126 simulation model algorithmic complexity, mean that quantitative indices of ACL kinetics and strains are now attainable alongside more traditional simulation parameters of joint and muscle 127 forces <sup>36</sup>. To date however, this more advanced modelling approach has not yet been utilized 128 129 to explore the effects of prophylactic knee sleeves on ACL loading and strain during high-risk sports specific football movements. Similarly, whilst the effects of prophylactic knee sleeve 130 have been examined previously, they have focused only on indices of knee joint loading/ 131 kinematics. Knee sleeves are likely to mediate both kinetic and kinematic alterations at more 132 than one body segment and thus at more than one joint; and potential positive alterations at the 133 knee joint mediated via the sleeve, may cause concurrent effects at other lower extremity joints. 134 Therefore, a more comprehensive approach also examining hip and ankle joint loading in 135 addition to knee joint kinetics would be of both practical and clinical relevance. 136

137

To summarize, there is currently no scientific investigation that has explored the effects of 138 prophylactic knee bracing on collective indices of ACL loading/ strains alongside lower 139 extremity joint loading using musculoskeletal simulation in football players. Therefore, the 140 aims of the current study were, using a two-experiment musculoskeletal simulation-based 141 142 approach (whilst measuring ACL biomechanics, knee joint kinematics and lower extremity joint loading) to examine the effects of both a prophylactic knee sleeve on 1. a sport specific 143 cutting movement in female university level footballers and 2. a single leg landing in male 144 university footballers. A study of this nature may provide further insight into the 145

146	comprehensive biomechanical effects of prophylactic knee sleeve designed to reduce the risk
147	from knee pathologies in football players.
148	
149	Methods

150	For both investigations, participants provided written informed consent and ethical approval
151	was obtained from the University of Central Lancashire, in accordance with the principles
152	documented in the Declaration of Helsinki. All participants were free from lower extremity
153	musculoskeletal pathology at the time of data collection and had not undergone surgical
154	intervention at the knee joint.
155	
156	<u>Knee sleeve</u>

A single nylon/silicone knee sleeve (Figure 1) was utilized in this investigation, (Kuangmi 1) 157 PC compression knee sleeve), was used in this study which came in three different sizes; 158 small, medium and large to accommodate all participants and was worn on the dominant 159 (right) limb in all participants. In accordance with Sinclair et al., <sup>28</sup>, at the end of data 160 collection participants were asked to subjectively rate the knee sleeve in relation to 161 performing the movements without the sleeve in terms of stability and comfort. This was 162 163 accomplished using 3-point scales that ranged from 1 = increased comfort, 2 = no-change and 3 = reduced comfort and 1 = increased stability, 2 = no change and 3 = increased stability. 164

167

168 *Experiment 1* 

169 *Participants* 

170	Twelve female (age $20.2 \pm 1.34$ years, height $1.61 \pm 0.06$ m, body mass $57.2 \pm 5.6$ kg and
171	$BMI = 22.1 \pm 3.0 \text{ kg/m}^2$ ) university first team level footballers volunteered to take part in the
172	current investigation.
173	
174	Procedure
175	Participants completed five trials of a $45^{\circ}$ cut movement in both experimental conditions
176	(sleeve and no-sleeve). Data collection was undertaken in 22 m long biomechanics laboratory,
177	using an a-priori approach velocity of $4.0 \pm 0.2$ m/s striking the force platform with their right
178	(dominant) limb. Cut angles were measured from the centre of the force platform and the
179	corresponding line of movement was delineated using masking tape so that it was clearly
180	evident to participants (Figure 2). The stance phase of the cut movement was defined as the
181	duration over $> 20$ N of vertical force applied to the force platform.
182	
183	@@@FIGURE 2 NEAR HERE@@@
184	
185	The order in which participants performed in each knee sleeve condition was counterbalanced
186	i.e. participant 1 performed first in the knee sleeve condition followed by the no-sleeve
187	condition whereas participant 2 was examined first in the no-sleeve condition followed by the
188	knee sleeve and so on and so forth. To ensure consistency, each participant wore the same
189	footwear (Asics, Patriot 6). Kinematic information was obtained using an eight-camera wall
190	mounted motion analysis system (Qualisys Medical AB, Goteburg, Sweden) with a capture
191	frequency of 250 Hz. The camera system was arranged in an umbrella-based configuration and
192	covered an 8 m length and 6 m width (Figure 2). To measure ground reaction forces (GRF), an

- operating at 1000 Hz was adopted. The GRF and kinematic information were synchronouslyobtained using an analogue board and interfaced using Qualisys track manager.
- 196

To define the anatomical frames of the thorax, pelvis, thighs, shanks and feet, passive 197 retroreflective markers of 19mm diameter were placed at the C7, T12 and xiphoid process 198 landmarks and also positioned bilaterally onto the acromion process, iliac crest, anterior 199 superior iliac spine (ASIS), posterior super iliac spine (PSIS), medial and lateral malleoli, 200 medial and lateral femoral epicondyles, greater trochanter, calcaneus, first metatarsal and fifth 201 202 metatarsal (Figure 3a). The hip, knee and ankle joint centre's were delineated according to previously established guidelines <sup>37-39</sup>. Carbon-fibre tracking clusters comprising of four non-203 linear retroreflective markers were positioned onto the thigh and shank segments. The foot 204 segments were tracked via the calcaneus, first and fifth metatarsal, the pelvic segment using 205 the PSIS and ASIS markers and the thorax via the T12, C7 and xiphoid markers. Static 206 calibration trials were obtained with the participant in the anatomical position in order for the 207 positions of the anatomical markers to be referenced in relation to the tracking clusters/markers, 208 following which those not required for dynamic data were removed. The Z (transverse) axis 209 was oriented vertically from the distal segment end to the proximal segment end. The Y 210 (coronal) axis was oriented in the segment from posterior to anterior. Finally, the X (sagittal) 211 axis orientation was determined using the right-hand rule and was oriented from medial to 212 lateral (Figure 3b). 213 214 @@@FIGURE 3 NEAR HERE@@@ 215 216 Furthermore, the effects of the prophylactic sleeve on knee joint proprioception were 217 investigated via a weight-bearing knee joint position sense test. In accordance with the 218

219	procedure of Sinclair et al. $^{29}$ , (with all of the above-mentioned retroreflective markers
220	remaining in place) participants stood in the centre of the motion capture system volume, on
221	one leg using the dominant limb. They then slowly squatted to a knee flexion angle of 30°,
222	which was verified using a handheld goniometer via same researcher throughout the testing
223	process. This position was held for a period of 15 s during which time the knee 'criterion' angle
224	was captured using the motion capture system (Figure 4ab). Following this, participants were
225	asked to return to a standing (i.e. with both feet on the floor) position for a further 15 s, and
226	then repeated the above process without guidance from the goniometer; a condition henceforth
227	named 'unaided'. This position was again held for a period of 15 s and the unaided trial was
228	similarly collected using the motion analysis system. This above process was undertaken on
229	three occasions in both prophylactic sleeve and no-sleeve conditions using a counterbalanced
230	order, and in between each trial participants walked a fixed distance of 20 ft to eliminate
231	proprioceptive memory of the previous trial.
232	

- 233

# @@@FIGURE 4 NEAR HERE@@@

234

235 Data Processing

Dynamic and proprioception trials were digitized using Qualisys Track Manager (Qualisys
Medical AB, Goteburg, Sweden) in order to identify anatomical and tracking markers then
exported as C3D files to Visual 3D (C-Motion, Germantown, MD, USA). GRF data and marker
trajectories were smoothed with cut-off frequencies of 50 Hz at 12 Hz respectively, using a
low-pass Butterworth 4th order zero lag filter. Within Visual 3D knee joint angles were
quantified using an XYZ cardan sequence (where X is the sagittal plane; Y is the coronal plane
and is Z is the transverse plane).

244	For the proprioceptive data, the knee flexion angle during the criterion and unaided trials was
245	calculated. The absolute difference in the knee flexion angle in degrees, was calculated between
246	the criterion and unaided trials to provide an proprioception angular error value for both the
247	prophylactic knee sleeve and no-sleeve conditions (with a low value indicates greater knee
248	proprioception) and then extracted for statistical analysis. For dynamic trials obtained during
249	the 45° cut movements, these were linearly normalized to 100 % of the stance phase. Three-
250	dimensional angular kinematic measures from the stance phase that were extracted from the
251	knee joint in each of the angular planes of rotation were peak angle, peak angular velocity and
252	minimum angular velocity.
253	
254	Dynamic data during the stance phase was exported from Visual 3D into OpenSim 3.3 software
255	(Simtk.org) using a custom pipeline that allowed the inverse kinematics to be exported to match
256	the degrees of freedom associated with the experimental model in OpenSim <sup>27</sup> . The standard
257	Gait2392 Opensim musculoskeletal model was adapted to include six degrees of freedom knee
258	joints and also an ACL bundles modelled in accordance with Sinclair et al., <sup>27</sup> as non-linearly
259	elastic passive soft tissues based on the proximal (femur) and distal (tibia) insertion points of
260	Xu et al., <sup>40</sup> (Figure 5ab). The model was further developed by incorporating a patella and the
261	tibiofemoral joint was separated into medial and lateral compartment locations which were
262	positioned at 25% and 75% of the scaled knee joint width in accordance with Barrios & Willson
263	<mark>41</mark> .
264	
265	@@@FIGURE 5 NEAR HERE@@@
266	
267	The model was firstly scaled within OpenSim to account for the anthropometrics of each

268 participant, using data from the anatomical landmarks collected during the static calibration

269	trials. In accordance with Kar & Quesada, <sup>35</sup> , muscle and ligament dimensions were scaled in
270	the same manner as body segments, from the static trial marker positions. Following this as
271	muscle forces are the main determinant of joint forces <sup>34</sup> , muscle kinetics were quantified using
272	computed muscle control (CMC) procedure to estimate a set of muscle force patterns allowing
273	the model to replicate the required kinematics.

275 Then, three-dimensional ankle, medial tibiofemoral, lateral tibiofemoral and hip joint forces as well as compressive patellofemoral joint forces were calculated via the joint reaction analyses 276 277 function within OpenSim, using the muscle forces generated from the CMC process as inputs. The joint reaction analysis function in OpenSim calculates the joint loads transferred between 278 two contacting bodies, about the joint location identified during the static trial. Furthermore, 279 280 the three-dimensional forces calculated at the lateral and medial aspects of the tibiofemoral joint via the joint reaction analysis were added together in order to also determine the total 281 tibiofemoral joint force in all three planes. In the current investigation, joint forces were 282 normalized by dividing by each participants body weight (BW). 283

284

From the above processing, peak three-dimensional ankle, lateral tibiofemoral, medial tibiofemoral, total tibiofemoral and hip joint forces, and peak compressive patellofemoral forces during the stance phase were extracted for statistical analyses. In addition, instantaneous load rates (BW/s) for each of the aforementioned joint loads were extracted by obtaining the peak increase in force between adjacent data points and joint force impulses (BW·ms) during the stance phase were also calculated using a trapezoidal function.

291

In addition to the above, from the CMC process firstly the peak ACL force during the stance phase was extracted and normalized by dividing the net values by bodyweight (BW).

Furthermore, the peak forces (BW) during the stance phase for the major muscles crossing the 294 knee joint were quantified and also the muscle force impulses (BW·ms) during the stance phase 295 were also extracted using a trapezoidal function. In addition, the biceps femoris long head, 296 biceps femoris short head, semitendinosus, semimembranosus muscle forces calculated via the 297 CMC process were added together to create the total hamstring muscle force. In addition, the 298 rectus femoris, vastus lateralis, vastus medialis and vastus intermedius forces calculated via the 299 CMC process were also summed to create the total quadriceps muscle force. The maximum 300 total hamstring and total quadriceps forces as well as their impulses during the stance phase 301 302 were extracted for statistical analysis.

303

In addition, the maximum ACL strain (%) was calculated by dividing the maximum ligament bundle length during the dynamic trials by the resting length, which was obtained during the static calibration trials <sup>35</sup> and ACL strain rate (%/s) was by obtaining the peak increase in ACL strain between adjacent data points.

308

309 *Statistical analyses* 

For each parameter/ condition, means and standard deviations were calculated and differences 310 between knee sleeve and no-sleeve conditions examined using Bayesian paired t-tests with 311 default prior scales using SPSS 27.0 software (SPSS, IBM). Bayesian factors (BF) were used 312 to explore the extent to which the data supported the alternative  $(H_1)$  hypothesis and Bayes 313 factors throughout were interpreted in accordance with the recommendations of Jeffreys <sup>42</sup> with 314 values  $\geq 3$  indicating sufficient evidence in support of H<sub>1</sub>. In the interests of conciseness and 315 clarity only variables that presented with Bayes factors  $\geq 3$  are presented in the results section. 316 Finally, using the data collected from the subjective feedback based on participants' ratings of 317 both stability and comfort were examined using Chi-Square tests. 318

- 320 *Experiment 2*
- 321 *Participants*
- 322 Ten male (age  $21.1 \pm 1.13$  years, height  $1.77 \pm 0.1$  m, body mass  $71.9 \pm 8.6$  kg and BMI =
- 323  $22.9 \pm 3.2 \text{ kg/m}^2$ ) university first team level footballers volunteered to take part in the current
- 324 investigation.
- 325
- 326 *Procedure*

327 Kinematic information was obtained using the procedure and biomechanical modelling 328 approach outlined in experiment 1 and participants once again wore the same footwear. For 329 this experiment participants performed single leg drop jump landings with their right 330 (dominant) limb after stepping off from a 30 cm plyometric box onto the force platform in 331 order to simulate deceleration phase of landing <sup>43</sup>. The landing phase of was considered to have 332 begun at foot contact (defined as > 20 N of vertical force applied to the force platform) and 333 ended at the instance of maximum knee flexion.

334

335 Processing

336 The same processing techniques and variables as experiment 1 were adopted.

337

338 *Statistical analyses* 

To examine biomechanical differences between conditions and subjective preferences/ ratings the same statistical analyses as experiment 1 were adopted, with the same statistical principles and reporting adhered to.

342

392	
393	Muscle forces
394	No differences in muscle forces (BF <3.0) were observed (Table 6).

## 396 *Subjective ratings*

For the ratings of comfort, participants indicated that the sleeve did not significantly influence subjective comfort ( $X^{2}_{(2)} = 1.75$ , p>0.05) or stability ( $X^{2}_{(2)} = 3.25$ , p>0.05).

399

## 400 Discussion

The current investigation using a two-experiment approach, represents the first study to explore the effects of prophylactic knee bracing on ACL loading/ strains alongside lower extremity joint loading using musculoskeletal simulation in male and female football players. The debilitating nature of ACL injuries, the high rate of re-injury and the incidence of degenerative joint disease secondary to ACL injury, means that this study may provide important information necessary to inform future prevention strategies and insight into the cumulative biomechanical effects of prophylactic knee braces.

408

In relation to the ACL, experiment 1 showed that ACL loading and ACL strain were larger in 409 the knee sleeve compared to no-sleeve. This observation opposes those of Sinclair et al., <sup>31</sup> and 410 Sinclair et al., <sup>32</sup> who showed that prophylactic knee bracing attenuated knee joint soft tissue 411 loading at the patellar tendon and ACL itself. Mechanically, aetiological analyses have shown 412 that ACL injuries occur when the ligament itself experiences excessive tensile forces and 413 strains <sup>12</sup>. Given the increases in these parameters shown in experiment 1, it appears that 414 prophylactic knee bracing akin to that examined in this study may increase the risk from the 415 416 ligamentous parameters linked to the aetiology of injury. Therefore, during the sports specific movements examined in experiments 1 and 2, the findings do not support the utilization of 417 prophylactic knee bracing for the attenuation ACL injuries. 418

420 At the tibiofemoral joint, experiment 1 indicated that lateral and total tibiofemoral compressive loading was larger in the knee sleeve. As no-differences in medial tibiofemoral compartment 421 loading were found it can be concluded that differences in total tibiofemoral loading were 422 mediated through increases at the lateral tibiofemoral compartment. Whilst prophylactic knee 423 bracing has been shown to attenuate tibiofemoral loading quantified using the peak knee 424 425 adduction moment during a badminton lung30, there has yet to be an examination of the effects of knee bracing on lateral tibiofemoral kinetics. Nonetheless, despite medial tibiofemoral 426 disorders being far more commonplace <sup>44</sup>, the aetiology of joint degenerative pathologies is 427 linked to excessive and habitual mechanical loading <sup>45</sup>. As such, experiment 1 indicates that 428 the knee sleeve may increase the risk from the biomechanical mechanisms linked to the 429 initiation of lateral tibiofemoral degeneration during the cut movement. Therefore, similar to 430 431 the conclusions in relation to the ACL, the findings do not support the utilization of prophylactic knee bracing for the attenuation of knee joint injuries in male and female 432 footballers during 45° cut and single leg landing conditions. 433

434

435 At the hip joint, the findings from experiment 1 showed that both the shear and medial force impulses were significantly larger in the knee sleeve condition compared to no-sleeve. This 436 observation supports the principles of the walking study shown by Toriyama et al., <sup>46</sup>, in that a 437 438 knee brace significantly attenuated hip joint kinetics of the ipsilateral side. This investigation therefore highlights that knee sleeves affect joint mechanics in addition to those experienced 439 by the knee joint itself. Thus, it is recommended that future analyses concerning knee braces, 440 441 examine more than knee joint biomechanics in order to obtain a more cumulative representation of their potential prophylactic effects. Regardless, as the aetiology of hip joint degeneration is 442

linked to the magnitude and frequency at which the applied mechanical loads are experienced
 <sup>45</sup>, experiment 1 indicates that the knee sleeve may enhance the risk from the kinetic
 mechanisms linked to the initiation of hip joint degeneration.

446

Previous systematic analyses have proposed that prophylactic knee braces promote and 447 facilitate safer landing biomechanics during functional athletic tasks by promoting an increased 448 sensation of knee joint stability <sup>47</sup>. However, the subjective and proprioceptive ratings from 449 both experiments in the current investigation provide only partial support for this notion. 450 Experiment 1 showed that the knee sleeve enhanced subjective knee joint stability yet in 451 experiment 2 there were no perceptual alterations as a function of the sleeve, and neither 452 investigation showed any improvement in knee joint proprioception. It is proposed that knee 453 braces enhance knee joint stability and proprioception by stimulating sense receptors in the 454 skin mediated through compression provided by the brace itself <sup>47</sup>. However, the findings from 455 456 experiment 1 do not appear to support this, as whilst improvements in perceived stability were 457 shown, this did not translate into positive changes in knee biomechanics. It has been speculated previously that prophylactic sleeves do not provide sufficient compression to alter knee 458 stability and proprioception sufficiently to mediate alterations in dynamic knee biomechanics 459 <sup>29</sup>. Therefore, although compression provided via the knee sleeve was not examined as part of 460 the current investigation, an interesting avenue for future analyses may be to explore devices 461 462 that provide different levels of compression in regards to their prophylactic efficacy.

463

A potential limitation to both experiments undertaken as part of the current investigation is the
 mechanism by which the musculoskeletal simulation-based analyses were completed. The
 CMC process, although an effective and robust tool for the quantification of muscle and soft

467	tissue kinetics utilized in previous analyses to simulate ACL mechanics <sup>35</sup> , can be limited in its
468	ability to quantify specific muscle coordination during dynamic tasks <sup>48</sup> . Furthermore, that the
469	ACL was not modelled with sex specificity in regard to its anatomy and scaling may serve as
470	a drawback to this investigation. Although such an approach has yet to be developed within the
471	simulation based musculoskeletal modelling literature; as the ACL contributes pointedly to
472	knee mechanics, incorporation of sex-specific ligament modelling may improve the efficacy of
473	musculoskeletal simulation analyses. Finally, that only relatively modest sample sizes were
474	utilized in both experiments may have limited statistical power and alternate statistical
475	observations may have arisen as a function of enhanced Bayes factors with the inclusion of
476	additional participants <sup>49</sup> .
477	
478	Conclusion
479	The current investigation adds to the literature by exploring via a two-experiment investigation,
480	the effects of prophylactic knee bracing on ACL loading/ strains and lower extremity joint
481	biomechanics using a musculoskeletal simulation-based approach in male and female
482	footballers. This study importantly showed in experiment 1 that ACL loading/ strain, lateral
483	and total tibiofemoral compressive forces as well as hip joint shear and medial forces were
484	greater in the knee sleeve condition and in experiment 2 that there were no statistical effects of
485	the knee sleeve. Therefore, the findings from the current investigation suggest that the
486	prophylactic knee sleeve examined in the current investigation does not appear to reduce the
487	biomechanical parameters linked to the aetiology of knee pathologies in male/ female
488	footballers.

## 641 Figure labels

- 642 Figure 1: Experimental knee sleeve.
- 643 Figure 2: Experimental laboratory set-up with motion capture system cameras numbered
- according to the laboratory system and force platform (FP). Approach (A) and cut (C)
- directions are labelled with arrows showing participants direction of travel as part of the 45°
- 646 cut movement.
- Figure 3: a. Experimental marker locations and b. trunk, pelvis, thigh, shank and foot segments,
- 648 with segment co-ordinate system axes (R = right & L = left), (TR = trunk, P = pelvis, T = thigh,
- 649 S = shank & F = foot, (X = sagittal, Y = coronal & Z = transverse planes).
- 650 Figure 4: Weight-bearing knee joint position sense test from a. frontal and b. sagittal
- 651 viewpoints.
- Figure 5: a. Experimental Opensim model in full and b. with only the ACL bundles visible.
